What is "Embedded - Microcontrollers"?

"Embedded - Microcontrollers" refer to small, integrated circuits designed to perform specific tasks within larger systems. These microcontrollers are essentially compact computers on a single chip, containing a processor core, memory, and programmable input/output peripherals. They are called "embedded" because they are embedded within electronic devices to control various functions, rather than serving as standalone computers. Microcontrollers are crucial in modern electronics, providing the intelligence and control needed for a wide range of applications.

I_{DD_BV}	CC	D	In-rush average current on V_{DD_BV} during power-up(5)	—	—	—	300 (6)	mA

1. V_{DD} = 3.3 V ± 10% / 5.0 V ± 10%, T_A = –40 to 125 °C, unless otherwise specified
2. This capacitance value is driven by the constraints of the external voltage regulator supplying the V_{DD_BV} voltage. A typical value is in the range of 470 nF.
3. This value is acceptable to guarantee operation from 4.5 V to 5.5 V
4. External regulator and capacitance circuitry must be capable of providing I_{DD_BV} while maintaining supply V_{DD_BV} in operating range.
5. In-rush average current is seen only for short time (maximum 20 µs) during power-up and on standby exit. It is dependant on the sum of the C_{REGn} capacitances.
6. The duration of the in-rush current depends on the capacitance placed on LV pins. BV decoupling capacitors must be sized accordingly. Refer to I_{MREG} value for minimum amount of current to be provided in cc.

The $|\Delta_{VDD(STDBY)}|$ and dVDD(STDBY)/dt system requirement can be used to define the component used for the V_{DD} supply generation. The following two examples describe how to calculate capacitance size:

Example 1 No regulator (worst case)

The $|\Delta_{VDD(STDBY)}|$ parameter can be seen as the V_{DD} voltage drop through the ESR resistance of the regulator stability capacitor when the I_{DD_BV} current required to load V_{DD_LV} domain during the standby exit. It is thus possible to define the maximum equivalent resistance ESR_{STDBY}(MAX) of the total capacitance on the V_{DD} supply:

$ESR_{STDBY}(MAX) = |\Delta_{VDD(STDBY)}|/I_{DD\_BV}$ = (30 mV)/(300 mA) = 0.1Ω [d]

The dVDD(STDBY)/dt parameter can be seen as the V_{DD} voltage drop at the capacitance pin (excluding ESR drop) while providing the I_{DD_BV} supply required to load V_{DD_LV} domain during the standby exit. It is thus possible to define the minimum equivalent capacitance C_{STDBY}(MIN) of the total capacitance on the V_{DD} supply:

$C_{STDBY}(MIN) = I_{DD\_BV}/dVDD(STDBY)/dt$ = (300 mA)/(15 mV/µs) = 20 µF

This configuration is a worst case, with the assumption no regulator is available.

Example 2 Simplified regulator

The regulator should be able to provide significant amount of the current during the standby exit process. For example, in case of an ideal voltage regulator providing 200 mA current, it is possible to recalculate the equivalent ESR_{STDBY}(MAX) and C_{STDBY}(MIN) as follows:

d. Based on typical time for standby exit sequence of 20 µs, ESR(MIN) can actually be considered at ~50 kHz.

released as soon as internal reset sequence is completed regardless of LVDHV5H threshold.

2. A device will be defined as a failure if after exposure to ESD pulses the device no longer meets the device specification requirements. Complete DC parametric and functional testing shall be performed per applicable device specification at room temperature followed by hot temperature, unless specified otherwise in the device specification.

3.20.3.2 Static latch-up (LU)

Two complementary static tests are required on six parts to assess the latch-up performance:

- A supply overvoltage is applied to each power supply pin.
- A current injection is applied to each input, output and configurable I/O pin.

These tests are compliant with the EIA/JESD 78 IC latch-up standard.

To preserve the accuracy of the A/D converter, it is necessary that analog input pins have low AC impedance. Placing a capacitor with good high frequency characteristics at the input pin of the device can be effective: the capacitor should be as large as possible, ideally infinite. This capacitor contributes to attenuating the noise present on the input pin; furthermore, it sources charge during the sampling phase, when the analog signal source is a high-impedance source.

A real filter can typically be obtained by using a series resistance with a capacitor on the input pin (simple RC filter). The RC filtering may be limited according to the value of source impedance of the transducer or circuit supplying the analog signal to be measured. The filter at the input pins must be designed taking into account the dynamic characteristics of the input signal (bandwidth) and the equivalent input impedance of the ADC itself.

In fact a current sink contributor is represented by the charge sharing effects with the sampling capacitance: being C_S and C_{p2} substantially two switched capacitances, with a frequency equal to the conversion rate of the ADC, it can be seen as a resistive path to ground. For instance, assuming a conversion rate of 1 MHz, with C_S+C_{p2} equal to 3 pF, a resistance of 330 kΩ is obtained ($R_{EQ} = 1 / (f_c \times (C_S+C_{p2}))$, where f_c represents the conversion rate at the considered channel). To minimize the error induced by the voltage partitioning between this resistance (sampled voltage on C_S+C_{p2}) and the sum of $R_S + R_F$, the external circuit must be designed to respect the *Equation 4*:

Equation 4

$$V_A \bullet \frac{R_S + R_F}{R_{EQ}} < \frac{1}{2} LSB$$

Equation 4 generates a constraint for external network design, in particular on a resistive path.
